A review of guidelines for cardiac rehabilitation exercise programmes: Is there an international consensus?

Kym Joanne Price¹, Brett Ashley Gordon¹,², Stephen Richard Bird¹ and Amanda Clare Benson¹

Abstract

Background: Cardiac rehabilitation is an important component in the continuum of care for individuals with cardiovascular disease, providing a multidisciplinary education and exercise programme to improve morbidity and mortality risk. Internationally, cardiac rehabilitation programmes are implemented through various models. This review compared cardiac rehabilitation guidelines in order to identify any differences and/or consensus in exercise testing, prescription and monitoring.

Methods: Guidelines, position statements and policy documents for cardiac rehabilitation, available internationally in the English language, were identified through a search of electronic databases and government and cardiology society websites. Information about programme delivery, exercise testing, prescription and monitoring were extracted and compared.

Results: Leading cardiac rehabilitation societies in North America and Europe recommend that patients progress from moderate- to vigorous-intensity aerobic endurance exercise over the course of the programme, with resistance training included as an important adjunct, for maintaining independence and quality of life. North American and European guidelines also recommend electrocardiograph-monitored exercise stress tests. Guidelines for South America and individual European nations typically include similar recommendations; however, those in the United Kingdom, Australia and New Zealand specify lower-intensity exercise and less technical assessment of functional capacity.

Conclusion: Higher-intensity aerobic training programmes, supplemented by resistance training, have been recommended and deemed safe for cardiac rehabilitation patients by many authorities. Based on research evidence, this may also provide superior outcomes for patients and should therefore be considered when developing an international consensus for exercise prescription in cardiac rehabilitation.

Introduction

Cardiovascular disease (CVD) is a leading contributor to global mortality and morbidity. Internationally, it is the cause of approximately a third of total yearly deaths,¹ with mortality rates in high-income countries ranging from 20% to 50%.²,³ CVD is responsible for approximately 20% of the worldwide disease burden.¹

Cardiac rehabilitation promotes secondary prevention of CVD and is an essential component of care for all cardiac patients.⁴,⁵ It is a coordinated physical, social and psychological intervention that favourably influences the underlying risk factors in order to stabilise, slow or reverse disease progression, and facilitates the ability of the patient to preserve or resume an active and functional contribution to the community.⁶,⁷

Cardiac rehabilitation promotes a healthy and active

lifestyle, with the aim of improving quality of life through: increased cardiac function; increased exercise tolerance; decreased cardiovascular symptoms; reduced levels of anxiety, depression and stress; return to work; and maintaining independence in activities of daily living. Structured exercise has been identified as being central to the success of cardiac rehabilitation.

Strong, consistent positive evidence exists for exercise-based cardiac rehabilitation for patients with stable angina pectoris, myocardial infarction (MI) and coronary revascularisation. Cardiac rehabilitation is also recommended for patients who have undergone heart transplant or valvular surgery, in addition to those suffering chronic heart failure. Meta-analyses have shown significant reductions in both all-cause and cardiac mortality from exercise-based rehabilitation compared to standard medical care without structured exercise training or advice, with the reduction associated with long-term rather than short-term follow-up. Exercise-based cardiac rehabilitation results in a significantly lower risk of fatal and non-fatal re-infarction through improved cardiac and coronary vascular function, as well as improved CVD risk factor profiles when compared to cardiac rehabilitation without an exercise component.

Cardiac rehabilitation services exist in fewer than 40% of countries throughout the world, with programmes available in 68% of the countries defined as high income by the World Bank. This figure falls to only 22% in low- and middle-income countries, where the majority of deaths due to CVD occur. The density of cardiac rehabilitation programmes varies from the equivalent of one programme for every 0.1 million inhabitants in the United States (US) to one programme for every 2.2 million inhabitants throughout Latin America and one programme for 164 million inhabitants in Bangladesh, where there is a single facility to service the entire population. Guidelines for the provision of cardiac rehabilitation have not been established in many of the nations providing this service.

The purpose of this review is to compare national guidelines for outpatient cardiac rehabilitation from around the world alongside those prepared by leading cardiovascular scientific societies, and provide insight into any differences and/or consensus in patient eligibility, programme delivery and exercise testing, prescription and monitoring that exist.

Methods

National guidelines, position statements and policy documents for exercise-based outpatient cardiac rehabilitation were searched from the earliest date available to July 2015 using PubMed and Google Scholar databases. The search terms “cardiac rehabilitation”, “guidelines”, “policy” and “position statement” were combined and searched alone and by country. Government and cardiology society websites for countries that were known to have cardiac rehabilitation services were also examined, along with reference lists of identified guidelines and review articles. Only those guidelines, position statements and policy documents available in English were included. Only resistance training recommendations for Germany have been published in English; however, guidelines covering all aspects of cardiac rehabilitation have been translated and summarised in a review article published by Karoff et al., and the information presented was utilised in the current review. Where non-English-language guidelines or position statements were located, the authors were contacted to confirm that an English version was not available. Document analyses of the guidelines, position statements and policy documents were undertaken to extract the relevant information for this review.

Results

Guidelines, position statements and policy documents for outpatient cardiac rehabilitation from 18 individual countries or regions were identified in the English language and included for review. The American Heart Association (AHA) and the American Association of Cardiovascular and Pulmonary Rehabilitation (AACVPR) have issued a joint scientific statement detailing the core components of cardiac rehabilitation programmes, with more comprehensive guidelines having been published by the AACVPR (with AHA endorsement). The Canadian Association of Cardiac Rehabilitation (CACR) have also developed detailed guidelines. A position statement has been prepared by the European Association of Cardiovascular Prevention and Rehabilitation (EACPR), with several individual European countries also producing their own guidelines. In the Australasian region, Australia and New Zealand each have their own guidelines, prepared by the respective National Heart Foundations, in conjunction with the Australian Cardiovascular Health and Rehabilitation Association (ACRA) in Australia. A joint position statement by the South American Society of Cardiology and the Inter-American Committee on Cardiovascular Prevention encompasses the whole of South America. In Asia, English-language cardiac rehabilitation guidelines have only been published in Japan. The World Health Organization (WHO) Expert Committee on Rehabilitation after Cardiovascular Diseases prepared guidelines for the provision of cardiac rehabilitation in 1993. This document has an emphasis on developing countries, but still contains information that is relevant...
to high-income countries. Published guidelines were also located for Brazil, Columbia, Cuba, Denmark, Estonia, Germany, Italy, Poland, Spain, Switzerland, Israel, and South Korea, but these have been excluded from this review as they were not available in English and funding was not available for translators.

Cardiac rehabilitation throughout the world follows the same progression from hospitalisation after an acute event through to recovery and on-going maintenance. Cardiac rehabilitation is commonly divided into either three or four phases, with the content of these phases varying between nations, as detailed in Supplementary Table 1.

**Programme eligibility and delivery**

Aspects of programme delivery detailed in cardiac rehabilitation guidelines include patient eligibility, pre-participation medical assessment, required personnel and responsibility for prescription and supervision of exercise and educational interventions (Supplementary Table 2). Acute coronary conditions that are eligible for cardiac rehabilitation are listed in Supplementary Table 2, while patients with peripheral arterial disease (PAD) are additionally included in the eligible patient lists for Austria, Europe, France, Ireland, Japan and South America. Medical and physical evaluations are recommended in all guidelines, with measurement of heart rate, blood pressure, body mass index and waist girth all being common. Furthermore, resting 12-lead electrocardiograph (ECG) prior to the commencement of cardiac rehabilitation is specified for Austria, Europe, France, Ireland, Japan and South America. Exercise and functional assessment

Technical exercise testing recommended in cardiac rehabilitation guidelines internationally, as shown in Tables 1 and 2. An ECG-monitored exercise stress test is recommended by the AHA and AACVPR, CACR and EACPR. Guidelines for Japan, South America and the majority of the European countries reviewed also include this recommendation for pre-programme exercise testing. Despite these recommendations by leading cardiovascular societies, less technical exercise testing, in the form of either a 6-minute walk test or shuttle walk test, form the standard for the determination of functional capacity in Australasia and the UK. However, these nations do acknowledge that an ECG-monitored exercise stress test should be performed for high-risk patients (those with decompensated heart failure, uncontrolled arrhythmias or experiencing angina at rest or with minimal exertion) or for patients wishing to participate in a high-intensity exercise programme (>75% maximal heart rate (HRmax)).

**Monitoring during exercise training sessions**

Heart rate monitoring and/or the Borg Rating of Perceived Exertion Scale are frequently recommended, with the monitoring of blood pressure during exercise and the observation of signs and symptoms, such as excessive breathlessness or fatigue, chest pain and light-headedness, also being widely specified. The AACVPR guidelines for the US have detailed a progression from continuous to intermittent ECG

monitoring over a number of sessions according to the risk level of the patient. These recommendations are also incorporated into the guidelines for Canada, Ireland and South America. The EACPR guidelines specify the use of ECG monitoring during the initial sessions of the rehabilitation programme and for patients experiencing new symptoms. The European countries France and Germany follow the recommendation of the EACPR, while the guidelines for Belgium and The Netherlands advise ECG monitoring only for high-risk patients, including implantable cardioverter–defibrillator (ICD) recipients and those with heart failure and a history of arrhythmias.

**Recommendations for exercise prescription in outpatient rehabilitation exercise programmes**

**Aerobic endurance training.** The recommendation for aerobic exercise is a feature of all of the international guidelines and position statements reviewed; however, differences are evident in the intensity of exercise, as well as the duration and frequency of training sessions (Tables 1 and 2).

Guidelines prepared by the leading scientific societies recommend that patients progress from moderate- to vigorous-intensity aerobic exercise, increasing to 80% of the maximal aerobic capacity (VO2max) or HRmax in the US18,19 and Europe, and 85% of the heart rate reserve (HRR) in Canada, over the course of their rehabilitation programme. With the exception of the UK39 and France, which specify moderate-intensity aerobic training only, individual European nations include progression to vigorous-intensity aerobic training as in the EACPR document. Similarly, South American guidelines correspond with those produced in North American nations. In comparison, the guidelines from Australia and Japan recommend that aerobic training sessions within the cardiac rehabilitation programmes should consist of light- to moderate-intensity exercise, with a maximum of 60% of the VO2max or HRR specified in Japan.

Aerobic interval training is proposed as an alternative to continuous aerobic exercise in the national guidelines for France, The Netherlands, Belgium, South America and Canada. However, there is no consensus on the optimal work-to-rest ratios for this type of training.

The frequency of aerobic exercise sessions recommended varies considerably between guidelines (Tables 1 and 2). The AHA, AACVPR, EACPR and CCR guidelines all recommend a minimum of three sessions per week. Within Europe, guidelines for the individual nations correspond with these recommendations, with the exception of the UK and Austria as exceptions. Conversely, the guidelines for Australia, Austria, and others specify a shorter rehabilitation programme length.
Resistance training. Detailed recommendations for resistance training are not routinely included in cardiac rehabilitation guidelines to the same level as aerobic exercise prescription (Tables 1 and 2). It is incorporated in the AHA and AACVPR guidelines, as well as those of the CACR and EACPR. All European nations and South America have included detailed recommendations for resistance training, with a separate document specifically for resistance training having been published for Germany. In comparison, resistance training is omitted altogether from the guidelines for Japan, while in Australia, New Zealand and Northern Ireland, there is limited prescription information to support the inclusion of resistance training.

Safety precautions for resistance training are incorporated into some guidelines. In Canada, the US, Germany, Ireland, Northern Ireland and Scotland, it is recommended that patients consistently participate in a supervised aerobic training programme for between 2 and 6 weeks without complications prior to commencing resistance training, in order to assess the patient’s response to exercise and to enable them to develop the skills to self-monitor their exercise intensity. In addition, the Northern Ireland and Scotland guidelines also specify that resistance training is only suitable for those patients who have been stratified into low- to moderate-risk categories (those without MI complications or exercise-related symptoms). All guidelines recommend that assessment prior to resistance training is via a multiple-repetition maximum test, which is less likely to lead to abdominal straining or blood pressure elevations than a single-repetition maximal strength test, but will still provide a baseline in order to guide prescription.

Resistance load is prescribed either as a percentage of the patient’s maximum strength as determined by their estimated one-repetition maximum, with this load varying between 30% and 80%, or based on the patient’s level of fatigue within the exercise set. The German recommendations (which are also incorporated into the Irish guidelines) include prescriptions for improving both muscular endurance and hypertrophy.

Flexibility training. Similar to strength training, flexibility training is not routinely specified as a component of the exercise programme for cardiac rehabilitation (Tables 1 and 2). The WHO guidelines, in addition to those for Austria, France and South America, include flexibility training as a recommendation, but prescription information is not stated. In comparison, the UK, US and Canadian guidelines detail the number of repetitions and duration of each stretch, and that flexibility training should be incorporated into the rehabilitation programme for two to three sessions each week.

Long-term maintenance of exercise training

Recommendations for the maintenance phase of cardiac rehabilitation, which commences once the patient has completed their outpatient programme, are incorporated into guidelines and position statements for the provision of outpatient cardiac rehabilitation (Supplementary Table 1), with the exception of Belgium. Specialised maintenance exercise programmes contribute to long-term cardiac health care and, in Germany, Canada and the US, may be conducted in rehabilitation facilities or hospitals with reduced supervision and monitoring, rather than what occurs in outpatient rehabilitation programmes. Otherwise, they might occur in community settings, as recommended in the UK and Australasia.

Recommendations for cardiac rehabilitation for different clinical conditions

Guideline documents for cardiac rehabilitation typically contain recommendations for exercise training common to all cardiac patients, with there being little variation in exercise prescription details between clinical conditions. However, in some instances, additional considerations relevant to specific patient groups are provided. Patients who have undergone cardiac surgery are recommended to avoid strenuous upper extremity exercise until the wound is stable. For both heart transplant and ICD patients, the use of target heart rate may not be appropriate for the determination of exercise intensity. Where heart rate is utilised for ICD patients, the target should be set at 10–20 beats per minute below the detection threshold of the device. Heart transplant patients undergoing corticosteroid therapy for rejection are recommended to discontinue exercise training during this treatment. Intermittent walking programmes are recommended for patients with PAD, with intensity governed by their claudication symptoms.

Heart failure, however, may be considered separately to other cardiac conditions. The AHA,
Discussion

Aerobic endurance training is the foundation for the exercise component of cardiac rehabilitation programmes. It improves cardiorespiratory fitness and functional capacity, reduces disease-related symptoms and favourably influences coronary risk factors, contributing to a reduction in mortality among MI survivors.\textsuperscript{19,20} Recommendations for aerobic endurance training are universally incorporated into guidelines for cardiac rehabilitation; however, the intensity at which this exercise should be performed varies between nations. Leading scientific societies for cardiac rehabilitation recommend a progression from moderate- to vigorous-intensity throughout the course of the rehabilitation programme.\textsuperscript{18–20,27} However, in Australia and the UK, recommendations are for light- to moderate-intensity aerobic exercise.\textsuperscript{22,32,33,39} This is also the recommendation of the WHO for developing countries, in which access to equipment for monitoring and training is restricted.\textsuperscript{4} In addition, countries in Australasia and the UK recommend less vigorous assessment of physical capacity prior to the commencement of a cardiac rehabilitation programme, rather than ECG-monitored exercise stress tests, as are standard in the guidelines of other nations.

Residential rehabilitation programmes, as are available in France, Germany and Austria, have been particularly successful. The testing and training equipment, along with the availability of highly trained staff in these programmes, make it possible for them to offer inpatient support to high-risk patients and provide high-intensity, high-frequency exercise rehabilitation sessions.\textsuperscript{5,17}

Ensuring patient safety throughout cardiac rehabilitation is paramount, and is more easily attained with lower-intensity exercise, which has a reduced reliance on technology and equipment for risk stratification and monitoring.\textsuperscript{4,6} Lower-intensity exercise also leads to reduced programme and implementation costs, and is thought to be more acceptable to a broader population, including older adults or those with physical limitations.\textsuperscript{3,6,47} Evidence for lower-intensity exercise\textsuperscript{6} is based on four randomised controlled trials conducted prior to 1999, reporting that higher-intensity exercise had small, positive relationships with maximal physical work capacity after the 8-week,\textsuperscript{48–50} 12-week,\textsuperscript{51} and 52-week\textsuperscript{47} interventions, and no significant differences were observed over the longer term.\textsuperscript{6} However, as cardiac patients may have a reduced exercise capacity and consequently perform daily activities at a higher percentage of their peak VO\textsubscript{2} compared with those without CVD,\textsuperscript{52} aerobic exercise interventions prescribed at higher relative intensities may be more beneficial for returning the patient to their previous capacities earlier.

Concerns have been raised in the literature as to the efficacy of cardiac rehabilitation in the UK (where moderate-intensity aerobic endurance exercise in two to three sessions per week is recommended\textsuperscript{50}) for improving patient mortality, morbidity and cardiac risk factors.\textsuperscript{53,54} Recent moderate- to vigorous-intensity interventions conducted with coronary artery disease patients in a supervised cardiac rehabilitation setting in Belgium,\textsuperscript{55} Italy,\textsuperscript{56–59} Germany,\textsuperscript{60} Canada,\textsuperscript{61} and the US\textsuperscript{62–65} resulted in significant improvements in exercise capacity (as measured by maximal exercise testing or field tests such as the 6-minute walk test and incremental shuttle walk test) in comparison to a non-exercising control group.\textsuperscript{55–57,61,64,65} Improvements in cardiovascular risk factors, including lipid profile,\textsuperscript{56,64} blood pressure,\textsuperscript{56,57,64} and body mass,\textsuperscript{64,65} were also reported. In comparison, light- to moderate-intensity training interventions have led to little or no improvement in exercise capacity\textsuperscript{66–68} and morbidity\textsuperscript{69} compared to non-exercising controls.

Dynamic resistance training is also beneficial for patients participating in cardiac rehabilitation, leading to an increase in physical strength and improved independence in activities of daily living, and positively influencing quality of life.\textsuperscript{31,70} Studies have shown that combined resistance training and aerobic training is superior to aerobic training alone in promoting increases in skeletal muscle mass, along with reductions in body fat via an improved resting metabolic rate.\textsuperscript{71} The addition of resistance training to a cardiac rehabilitation programme may also optimise responses to aerobic training as a result of increased muscle strength, leading to more favourable effects on exercise capacity.\textsuperscript{71} Despite this evidence, aerobic training is still the primary focus of many guidelines for cardiac rehabilitation internationally, with complete prescription details for resistance training included in only 11 out of 18 of the guidelines that were reviewed, perhaps due to a perceived risk of complications as a result of
blood pressure increases during resistance training. While there are some cardiovascular conditions that contraindicate resistance training, the AHA have issued a scientific statement detailing that resistance training can be initiated at a low intensity, provided patients have a functional capacity of ≥4 metabolic equivalents (METs). This recommendation, along with that which is included in several guidelines for patients to first complete a period of supervised aerobic training in order to ensure safety, lend strength to the inclusion of resistance training as a core component of cardiac rehabilitation exercise programming.

Exercise testing is a widely employed component of patient assessment prior to the commencement of cardiac rehabilitation. The main scientific societies for cardiac rehabilitation, including the AHA, AACVPR, EACPR and CACR, strongly recommend that patients undergo a symptom-limited, ECG-monitored exercise stress test in order to identify any abnormal signs or symptoms present during exercise and determine any contraindications to higher exercise intensities, in addition to establishing peak exercise capacity in order to enable individualised exercise prescription. However, guidelines for countries in Australasia and the UK recommend such formal testing of exercise capacity only for high-risk patients or those undertaking a high-intensity exercise programme, while low- to moderate-risk patients are instead assessed using submaximal tests, such as timed walk tests. Timed walk tests, which include the 6-minute walk and incremental walk tests, are not considered to be equivalent substitutes for traditional exercise testing, as intensity of effort may be variable due to the self-pacing nature of the test, and outcomes correlate only modestly with VO2max. Both the 6-minute walk test and incremental shuttle walk test may also exhibit a ceiling effect in patients with high levels of physical performance, where stride length or maximal walking speed may limit their performance.

Although ECG monitoring of exercise training sessions is not associated with the rate of adverse events, its use is beneficial in detecting significant exercise-induced changes, monitoring patient compliance with respect to heart rate and increasing patient self-confidence. However, the use of ECG monitoring does not eliminate the need for educating patients in self-monitoring techniques. The AACVPR have provided recommendations for the level of ECG monitoring based on the risk level of the patient and their progress through the programme, commencing with continuous monitoring and decreasing to intermittent monitoring as appropriate. These recommendations allow a balance to be achieved between patient safety and increased programme cost as a result of ECG use. In contrast, the majority of other guidelines for cardiac rehabilitation recommend ECG monitoring only for high-risk patients or those in the early stages of their participation.

Ongoing physical activity and the maintenance of health-related lifestyle changes are required in order to sustain the beneficial effects of a cardiac rehabilitation programme. Longitudinal training studies have demonstrated that supervised exercise performed over a number of years maintains functional capacity in patients with coronary artery disease or chronic heart failure. Ten years of moderate exercise training was found to additionally improve quality of life in individuals with heart failure, while 7 years of moderate- to vigorous-intensity training in coronary artery disease patients was also shown to improve lipid profiles. Separate guidelines for the maintenance phase of cardiac rehabilitation are not available. Instead, this is incorporated briefly into the recommendations for outpatient rehabilitation programmes – in all countries except Belgium – in the form of encouragement to continue with regular physical activity in order to meet physical activity guidelines, with referrals to home walking programmes or attendance at local gymnasiums, sports clubs or community groups.

Conclusion

Key cardiology and cardiac rehabilitation organisations, including the AHA, AACVPR, CACR and EACPR, endorse a progression from moderate- to vigorous-intensity aerobic exercise in conjunction with resistance training in order to obtain improvements in functional capacity, physical strength, cardiac risk factors and quality of life. This higher-intensity exercise prescription recommendation is supported by ECG-monitored exercise stress testing prior to programme commencement as standard practice, as well as the use of ECG monitoring during exercise training sessions in the AACVPR guidelines, in order to ensure the safety of participants and individualised exercise prescription. In comparison, the guidelines throughout Australasia, the UK, France and Japan recommend lower-intensity aerobic exercise and/or less technical exercise testing, with a reduced focus on resistance training.

While a reduced reliance on equipment and technology in lower-intensity exercise programmes may increase the accessibility of these cardiac rehabilitation programmes, exercise interventions in coronary artery disease patients based on recommendations of moderate to vigorous intensity have shown greater improvements in cardiorespiratory fitness and cardiac risk factors than lower-intensity interventions, when compared to usual care without an exercise component. The superior outcomes and demonstrated safety of
these higher-intensity interventions lend support for an international consensus for exercise prescription in cardiac rehabilitation programmes to include higher-intensity aerobic exercise in conjunction with resistance training, following ECG-monitored exercise stress testing and exercise monitoring. Countries that recommend lower-intensity aerobic exercise with a minimal focus on resistance training should look to reviewing the recent evidence and consider the potential of modifying their recommendations where the cost is not prohibitive.
